## **Introduction**

The Cornwall RAP committee has selected a site in east Cornwall opposite the Courtauld's plant for a contaminated-sediment removal project. This is an area of highly variable surface sediments (Rukavina 1993) in which levels of heavy metals are known to exceed the severe-effect-level criteria (Beak 1993; Biberhofer (Environment Canada), pers commun.) Good estimates of fine-sediment distribution and volume are required to permit selection of the appropriate technology for dredging and to estimate the costs of dredging and treatment.

The present study was undertaken to provide detailed direct measurements of sediment thickness and sediment type within a contaminated 1-hectare area just east of the Courtauld's pump house. Divers measured the sediment thickness by probing to refusal at 91 sites and characterized them in terms of water depth, grain size and weed cover. A smaller area with thicker sediment at the east end of the survey area was selected for an analysis of the distribution of thickness and sediment types and for GIS analysis of sediment volume. This report provides maps and data on sediment distribution and a preliminary estimate of sediment volume.

## **Survey Methods**

Bottom sampling and underwater television and acoustic surveys by NWRI in 1993 showed the entire north-shore reach between Windmill Point and Pilon Island to be a very complex mix of muds, sands and gravels, weed beds and scattered cobbles and boulders (Rukavina 1993). Because the bed materials are so variable, it was decided to limit the current survey to a small area which could be mapped in detail and to use diver surveys to collect direct measurements of sediment properties. The survey was carried out during the weeks of June 20 and July 4, 1994. Data were collected at 91 sites.

The survey vessel was the Canadian Hydrographic Survey launch Pintail which is equipped for diving operations. Because of the need to limit diver contact with the bottom sediments, the divers were not free-swimming but worked from a platform suspended below the launch at a height of 30-50 cm above the bottom. The platform and diver stayed in place as the boat was moved from site to site. For safety reasons, the launch was anchored fore and aft and onshore and offshore and navigation was accomplished by adjusting anchor lines to produce a series of sample arcs across the survey area. Although this produces an irregular grid of samples, it does permit safe and fast collection of data and optimal use of diver time. With experience, it is possible to sample a site and move to the next site in 5 to 10 minutes. The only serious limitation of the procedure is that the need for clearance of the diver stage restricts the minimal depth of operation to about 3 m and does not permit measurements in the inner 25 to 50 m of the inshore zone.

Sites were located with a shore-based Navitrack laser-positioning system which is capable of 0.3-0.6 m accuracy. Fixes were taken from a target located directly above one corner of the diver platform and are considered to be accurate to within 1-2 m. A simple mapping program written in BASIC was used to track boat position and select sites from a real-time display of the survey area and to compute and log position data in UTM coordinates.

The Navitrack instrument position was originally located approximately with reference to the limited control data available. Corrections were applied later from a third-order traverse of available control points along the reach from

## **Introduction**

The Cornwall RAP committee has selected a site in east Cornwall opposite the Courtauld's plant for a contaminated-sediment removal project. This is an area of highly variable surface sediments (Rukavina 1993) in which levels of heavy metals are known to exceed the severe-effect-level criteria (Beak 1993; Biberhofer (Environment Canada), pers commun.) Good estimates of fine-sediment distribution and volume are required to permit selection of the appropriate technology for dredging and to estimate the costs of dredging and treatment.

The present study was undertaken to provide detailed direct measurements of sediment thickness and sediment type within a contaminated 1-hectare area just east of the Courtauld's pump house. Divers measured the sediment thickness by probing to refusal at 91 sites and characterized them in terms of water depth, grain size and weed cover. A smaller area with thicker sediment at the east end of the survey area was selected for an analysis of the distribution of thickness and sediment types and for GIS analysis of sediment volume. This report provides maps and data on sediment distribution and a preliminary estimate of sediment volume.

## **Survey Methods**

Bottom sampling and underwater television and acoustic surveys by NWRI in 1993 showed the entire north-shore reach between Windmill Point and Pilon Island to be a very complex mix of muds, sands and gravels, weed beds and scattered cobbles and boulders (Rukavina 1993). Because the bed materials are so variable, it was decided to limit the current survey to a small area which could be mapped in detail and to use diver surveys to collect direct measurements of sediment properties. The survey was carried out during the weeks of June 20 and July 4, 1994. Data were collected at 91 sites.

The survey vessel was the Canadian Hydrographic Survey launch Pintail which is equipped for diving operations. Because of the need to limit diver contact with the bottom sediments, the divers were not free-swimming but worked from a platform suspended below the launch at a height of 30-50 cm above the bottom. The platform and diver stayed in place as the boat was moved from site to site. For safety reasons, the launch was anchored fore and aft and onshore and offshore and navigation was accomplished by adjusting anchor lines to produce a series of sample arcs across the survey area. Although this produces an irregular grid of samples, it does permit safe and fast collection of data and optimal use of diver time. With experience, it is possible to sample a site and move to the next site in 5 to 10 minutes. The only serious limitation of the procedure is that the need for clearance of the diver stage restricts the minimal depth of operation to about 3 m and does not permit measurements in the inner 25 to 50 m of the inshore zone.

Sites were located with a shore-based Navitrack laser-positioning system which is capable of 0.3-0.6 m accuracy. Fixes were taken from a target located directly above one corner of the diver platform and are considered to be accurate to within 1-2 m. A simple mapping program written in BASIC was used to track boat position and select sites from a real-time display of the survey area and to compute and log position data in UTM coordinates.

The Navitrack instrument position was originally located approximately with reference to the limited control data available. Corrections were applied later from a third-order OLS survey arranged by contract. Five intervisible control points along the reach from the Tank Farm to Pilon Island are now available for future surveys.

Divers measured sediment thickness by pushing a calibrated stainless-steel rod into the bottom sediment to refusal and reading its penetration. The rod was marked at 5-cm intervals and readings are considered to be accurate to  $\pm 2$  cm. Four readings

were taken, one at each corner of the dive stage, an 8 ft x 4 ft platform with its short dimension oriented parallel to the boat keel. Divers also estimated the sediment grain size and the percentage of bottom cover by weeds or boulders, and noted other bottom features including the release of gas bubbles from the sediment during probing and the firmness of the substrate below the soft-sediment cover. Water depth at each site was recorded to the nearest 0.3 m on an echo sounder corrected for transducer draft but not for water temperature. Depths are relative to the water level at the time of survey and have not been adjusted to the Great Lakes datum.

Figure 1 shows the distribution of sites. The large rectangle is the area originally specified for survey. When it became clear from the early data that the area was too large to cover in the time available, the survey was shifted to the smaller polygon further east and data were collected at 54 sites in the smaller area.

## Results

Figure 2 is a classification of bottom type based on the diver observations. Sediments have been subdivided into five types: 1) silt (fine-grained sediment of silt or clay size), 2) slightly coarser sandy silts, 3) weed beds on fine sediment, 4) a mixed bottom of boulders, cobbles or gravel, and fine sediments and 5) a mixed bottom of weeds and fine and coarse sediments. Bed materials in the western half of the polygon are mainly types 3, 4 and 5. The eastern half consists of more uniform silts and sandy silts with only minor weed cover and no coarser materials. The curved line which divides the polygon is the approximate boundary between the two bottom types. The inshore area was not surveyed because it was too shallow but several launch traverses across it showed it to be mainly weed and boulder bottom with little fine sediment cover.

Water depth in the polygon ranges from 2.4 to 7.7 m and averages 5.3 m (Figure 3). The offshore profile has a low slope from the shoreline to a depth of about 4 m, steepens from 4 to about 7 m, and then flattens again beyond that depth. Profile slope increases across the area from southwest to northeast.

Figures 4 and 5 are maps of sediment thickness and variability in thickness. The data in Figure 4 are the averages of the 4 measurements taken at each site. Figure 5 shows the variability at each site expressed in terms of standard deviation. Sediment thickness within the polygon ranges from 9 to 69 cm and standard deviation from 0 to 31 cm. Average thickness is 33.6 cm. There is considerable variation in thickness between sites and a general trend of increasing thickness from southwest to northeast. The substrate below the soft-sediment cover is generally hard and likely represents buried boulders or cobbles since divers observed no bedrock exposures in the river bed. There were also a few instances of underlying gravel or stiff clay.

Penetration of the sediment often resulted in the release of gas bubbles which may be methane produced by decomposition of organic material. Figure 6 shows the sites at which gas was observed. The gas tends to be associated with thicker sediments but does not appear to be related to weed cover or sediment texture.

In water depths greater than 5 m, divers observed a black fibrous coating of the sediment which ranged in thickness from a few mm to a few cm. They described it as having the appearance of a motheaten carpet. No samples were taken and it is not clear whether the material is an algal layer or an industrial byproduct. Figure 7 shows estimates of bottom coverage of the material. Its distribution is limited to the offshore portion of the polygon and it does not coexist with weed beds.

Detailed listings of the data discussed above have been tabulated in appendices 1 and 2. Appendix 1 lists the information on date, position, water depth and diver notes. Appendix 2 is a listing of all sediment data.

## **Estimate of Sediment Volume**

A preliminary estimate of the volume of sediment within the polygon has been obtained by using simple descriptive statistics (Appendix 3). Results should be used with caution. Because the thickness distribution is skewed towards lower values, its mean and standard deviation may not be reliable measures of average thickness and of the error in the thickness estimate.

Appendix 3 lists all the thickness data for the sites within the polygon and the summary statistics derived from them by assuming that they are normally distributed. Mean sediment thickness computed as the mean of site means is 33.6 cm and the standard deviation of site means is 18.3 cm. The 95% confidence interval for the mean is  $\pm 4.9$  cm. This indicates that there is a 95% probability that the true mean value for sediment thickness falls within the interval  $33.6 \pm 4.9$  cm.

The area of the polygon is 7563 m<sup>2</sup>. The sediment volume is computed as the product of the area and mean thickness. The resultant volume is 2541 m<sup>3</sup> and the extreme values based on the 95% confidence interval for thickness are 2172 m<sup>3</sup> and 2910 m<sup>3</sup>. Note that this estimate uses an equal weighting for each thickness value and does not take into account the nonuniform distribution of the samples. The error in measurement of  $\pm 2$  cm has also been ignored for this preliminary estimate.

## **Conclusions**

New data on sediment type and thickness at the proposed Cornwall dredge site have been used to map the distribution of bottom materials and to estimate the volume of fine-grained contaminated sediments. Bottom-sediment type tends to be a mix of fine sediments, weeds, and boulders in the western half of the area, and more uniform silts and clays in the eastern half. Gas is present at most of the eastern sites and a thin

black fibrous mat of unknown origin is common in the southeastern part of the area. Sediment substrate is generally hard (boulders?) and less commonly stiff clay or gravel.

Sediment thickness ranges from 6 to 73 cm across the area and varies by as much as 65 cm at individual sites. The mean thickness determined by simple averaging without weighting for site distribution is  $33.6 \pm 4.9$  cm and the associated wet-sediment volume is  $2541 \pm 369$  m<sup>3</sup>. It should be possible to improve the estimate of volume by subjecting the same data to areal analysis in a GIS (geographic information system) where it is possible to deal with the site thicknesses and areas associated with them individually (Rukavina and Delorme 1992) . This will be the subject of a separate report.

## **Acknowledgements**

Diving operations were coordinated by H. Don, the NWRI dive officer, and carried out by NWRI divers B. Gray, M. Dahl and T. Breedon. The Central Region of the Canadian Hydrographic Service supplied the Navitrack Positioning System and the assistance of P. Millette in setup and training. B. Trapp of the New Technologies Research Branch, NWRI, assisted in the second part of the survey. H. Biberhofer, Ecosystem Health Division, Environment Canada, arranged for the survey of shore-reference sites and advised on the format and content of the report. Funding for the survey was arranged by J. Anderson of the Environment Canada's Restoration Programs Division.
